Abstract. The staggered model is a recent, very general variant of discrete-time quantum walks which, avoiding the use of a coin to direct the walker evolution, explores the underlying graph structure to build an evolution operator based on local unitaries induced by adjacent vertices. Indeed, unlike conventional, coin-based quantum walks, which proceed straightforwardly from one vertex to another, the staggered variant takes advantage of forming partitions of graph cliques over the graph structure of the walking space. Then, it combines local evolution operators corresponding to different partitions along discrete time steps. Optimizing the implementation of staggered walks in order to increase resilience to decoherence phenomena motivates their analysis with the ZX-calculus, an exercise that is the object of this short paper. As expected, the calculus rewrote the original circuit, significantly reducing the number of (expensive) gates used. Moreover, the exercise identified an underlying pattern leading to an alternative, potentially more efficient evolution operator.

1 Introduction

Thought of as the quantum counterpart to classical random walks, quantum walks [VA12] provide an interesting technique in algorithmic design, with applications in unstructured search, graph algorithmics and communication protocols.

Differently from the classical case, where the walker next move follows the result of some sort of random choice, in a quantum setting evolution typically proceeds in an equally weighed superposition of possible moves through the iteration of a unitary operator, without resorting to intermediate measurements. This results in a very rich dynamics, in which the design of the evolution operator, and even seemingly innocent differences in its phase and in the initial state, determine complex 'walking patterns' which differ greatly both among them and in contrast to the classical setting.

The relevance of quantum walks as a tool for algorithmic design justifies both a better understanding of their behaviour and the optimization of their implementation, namely to increase resilience to decoherence phenomena. This short paper resorts to the ZX-calculus [CD08,vdW20,CHKW22] for such a purpose. The ZX-calculus is a diagrammatic language for reasoning about linear maps between qubits. It is based on generators — the *spiders* — that generalise rotations over

---

the Z and X basis, and sets of rewrite rules whose completeness means that equality between linear maps can be proven diagrammatically. This allows for program transformation in quantum software engineering, guided by powerful circuit optimisation strategies for e.g. T-count reduction and gate compilation.

The exercise reported here focus on a recent, very general variant of discrete-time quantum walks — the *staggered* model [PSFG16] — which, avoiding the use of a coin to direct the walker evolution, explores the underlying graph structure to build an evolution operator based on local unitaries induced by adjacent vertices. The model is reviewed in Section 2. Then, in Section 3, its standard circuit implementation is translated and rewritten in ZX, supported by the *PyZX* tool [KvdW20a]. This process leads in Section 4 to the identification of a diagrammatic pattern providing an interesting approximation to, and in some cases, more efficient version, of the underlying evolution operator.

2   Staggered quantum walks

In contrast to conventional, coin-based quantum walks, which proceed straight-forwardly from one vertex to another, the staggered variant [PSFG16] takes advantage of forming partitions of graph cliques[1] over the graph structure of the walking space. Each partition forms a tesselation whose elements do not overlap. The set of cliques in each tessellation must cover all vertices of the graph, and the set of tessellations $\{T_1, T_2, ..., T_k\}$ chosen must cover all the edges.

Then a unit vector, typically encoding a uniform superposition, is associated to each clique so that the vector belongs to the subspace spanned by the corresponding vertices. I.e.,

$$\left| u_j^k \right\rangle = \frac{1}{\sqrt{|\alpha_j^k|}} \sum_{l \in \alpha_j^k} |l\rangle , \qquad (1)$$

where α_j^k is the jth polygon in the kth tessellation.

This way each tessellation k gives rise to an operator

$$H_k = 2 \sum_{j=1}^{p} \left| u_j^k \right\rangle \left\langle u_j^k \right| - I. \qquad (2)$$

which propagates the probability amplitude locally, in each clique. The composition of all such operators defines the evolution operator, which, by solving the the time-independent Schrodinger equation, is equivalent to

$$U = e^{i\theta_k H_k} ... e^{i\theta_2 H_2} e^{i\theta_1 H_1}, \text{ where } e^{i\theta_k H_k} = \cos(\theta_k) I + i \sin(\theta_k) H_k \qquad (3)$$

since $H_k^2 = I$, meaning that the Hamiltonian is a reflection operator that, when expanded in a Taylor series, generates a local operator.

---

[1] A clique is a subset of vertices of an undirected graph such that every two distinct vertices are adjacent.

As an elementary example consider a line where the following two tessellations (depicted in red and blue below) are defined

$$T_\alpha = \{\{2x, 2x+1\} \colon x \in \mathbb{Z}\} \text{ and } T_\beta = \{\{2x+1, 2x+2\} \colon x \in \mathbb{Z}\}. \qquad (4)$$
Thus,

$$|\alpha_x\rangle = \frac{|2x\rangle + |2x+1\rangle}{\sqrt{2}} \text{ and } |\beta_x\rangle = \frac{|2x+1\rangle + |2x+2\rangle}{\sqrt{2}}, \qquad (5)$$

yielding Hamiltonians

$$H_\alpha = 2 \sum_{x=-\infty}^{+\infty} |\alpha_x\rangle \langle \alpha_x| - I \text{ and } H_\beta = 2 \sum_{x=-\infty}^{+\infty} |\beta_x\rangle \langle \beta_x| - I. \qquad (6)$$

Therefore, $U = e^{i\theta H_\beta} e^{i\theta H_\alpha}$ is the evolution operator. The probability distribution on a line after 50 steps, starting at $|+\rangle$, for different values of θ, is depicted below, noticing that the walker is more likely to be found further away from the origin as the angle increases.

,

3   Bringing ZX into the picture

A circuit implementation of the staggered model can be found in [San21]. As expected, it resorts to the joint tessellation dynamics, in contrast to a coined quantum walk that uses a coin as a shift operator. For the example discussed above, it yields
where $R_x(\theta) = e^{\frac{-i\theta X}{2}}$ and the Inc(rement) and Dec(rement) circuits have the usual implementation through generalized Toffoli gates. An implementation for a 3 qubit staggered quantum walk, starting at $|4\rangle$ and taking $\theta = \frac{\pi}{3}$, which maximizes propagation, is represented in a ZX diagram as

which takes advantage of the ZH-calculus H-box notation for representing Toffoli gates in a concise way. Expanding Tofolli into its basic gates leads to
Some simple optimizations can be considered to deal with the CNOT gate at the end of the expansion of the Toffoli gate and the CNOT belonging to the increment operator, and similarly, but for a X-spider between the CNOT targets, in the decrement operator. Moreover, one may cancel the two X-spiders with phase π in the first qubit between the increment and decrement layers, and the two consecutive Hadamards in the last qubit. The result is the following ZX-diagram,
These optimizations slightly reduced the number of Clifford gates in the diagram. More advanced techniques, described in [KvdW20b] and directly implemented in *PyZX* [KvdW20a] as the `full_reduce` method, may reduce the circuit T-count in about 50% [KvdW20b]. Although this is not the case for our small example, when we start applying such simplifications to staggered models with larger amounts of steps the T-count reduction can reach appproximately 60-70%. Back to the example, this simplification yields
This diagram no longer resembles a circuit, making difficult a comparison with the original one. The circuit extracted [dBKvdW22] by *PyZX* has more gates than the one obtained from the simple optimizations mentioned above, although the T-count is indeed smaller.

In fact, the `full_reduce` method introduces several additional Hadamard gates to make all the edges Hadamard-edges, and color-change all the X-spiders. The subsequent circuit extraction 'preserves' the nature of the *graph-like* ZX-diagram. As such there are a lot of Hadamard gates and Z-spiders that could cancel-out or color-change. Following the extraction with a small set of simplifications, basically resorting to fusion rewrite rules followed by color-changes, we get a much smaller circuit.

This fully-simplified circuit now surpasses the original circuit in both the total amount of gates and T-count, but not the one obtained with the simple optimizations above. Although the reduction of both these metrics are not that significant in this example, when applying the same techniques in models with a greater number of steps reductions in the number of gates and T-count become quite clear. The following tables show, respectively, the total number of gates and the T-count value induced by the different optimization procedures used.

	Number of steps in the staggered quantum walk:			
Optimizations used:	1	2	4	8
None	39	77	153	305
Simple	31	59	115	227
Full-reduce + fusion/id/to_rg	37	47	72	118

|	Number of steps in the staggered quantum walk:			
Optimizations used:	1	2	4	8
None	16	32	64	128
Simple	16	32	64	128
Full-reduce + fusion/id/to_rg	10	16	28	52

4 An alternative evolution operator

When analyzing the ZX diagram for long staggered quantum walk (i.e. with more than 5 steps) a pattern starts to emerge, repeating itself as many times as the number of steps in the quantum walk. It seems able to represent, or at least to approximate, both the increment and decrement layers of the evolution operator. Its ZX representation is

where $\alpha_n = \pm\frac{\pi}{4}$ and $\beta_n = \frac{2\pi}{3} + n\pi$, with $n = 0$ or $n = 1$.

There is also a slight variation of this operator, where a CNOT gate between the first and last qubit appears right after the β_1 Z-spider.
This diagram does not fully capture the staggered model we started with, but, once suitably enveloped, it captures the exact same tensor as the original circuit. The set of gates to be placed as an envelop, in the beginning and the end of the diagram, does not exhibit a specific structure, but for 4 rotations combined with a seemingly random arrangement of other phase-less gates.

This construction appeared when optimizing the 3 qubit staggered quantum walk. However, it can be generalized for an n qubit implementation, yielding the following operator, in the form of a ZX-diagram:
This operator is defined by entangling the first and last qubits and placing them in superposition. This is achieved by the XCX-gate (which is a CNOT with a Hadamard on both sides of the control), followed by a CNOT gate between the first and last qubits and a rotation over the X-axis on the first one. Then follows a ladder of XCX-gates starting with the first qubit and the $n - 1^{th}$ qubits and descending all the way to the second one. This is followed by a rotation over the Z-axis along with a X-axis rotation. Then a CNOT is applied to the first and last qubits, followed by a X-axis rotation and a XCX-gate over the first qubit and

the $n - 1^{th}$ one. Finally, there is a second Z-axis rotation followed by the same ladder of XCX-gates, now appearing between the first and the $n - 2^{th}$ qubits and descending all the way to the second. And, finally, a last X-axis rotation.

The rationale behind this operator is easy to explain: it creates a uniform distribution over a certain number of states, applies a rotation that makes some states more likely than others and then spreads these probabilities over the remaining states using CNOT gates. This also explains why the pattern only shows up in staggered quantum walks over a certain length. The classical evolution operator resorting to the increment and decrement layers, needs to be repeated a number of times to be able to spread the probability distributions over the whole state space. This is what this version does on the first layer. Thus, it cannot approximate staggered quantum walks with a small number of steps as well as it can for longer ones.

In any case, this alternative implementation has a number of advantages. First and foremost it reduces the total amount of gates needed to represent the evolution of the quantum walk. With the number of qubits increasing so does the cost of the increment and decrement layers, as a n qubit staggered quantum walk needs to implement MCX gates with $n - 1$ controls. Then, such MCX gates need to be expanded into their basic gates representation [Sle06]. The alternative operator uses at most gates controlled by at most 1 qubit. Moreover, to go from a n to a $n + 1$ qubit quantum walk, all that needs to be done is to add two more XCX-gates, one to each ladder of XCX-gates. Such is not the case of the evolution operator based on increment and decrement layers.

In general, this makes the alternative operator much more efficient with respect to the total number of gates used, leading to lower depth and, therefore, potentially less error-prone circuits.

As mentioned above, just by itself this operator is able of approximating the evolution of a staggered quantum walk. Although the approximation is not perfect it can yield results which are quite similar to the ones obtained with the original implementation of the staggered model, as shown in the graph below.
One particular advantage of this alternative evolution operator is that it can work quite well on a quantum processor with limited connectivity. This is due to the fact that all the qubits used in the staggered quantum walk only need to be strongly connected to the first qubit, thus minimizing possible errors occurring from having to operate on two qubits with poor connectivity.

However, a number of challenges remain, requiring further investigation. These concern the most suitable choice of parameters for α_n and β_n, as well as whether and how they depend on the number of qubits used in a particular staggered walk. Actually, when optimizing the 4 qubit implementation of this circuit the resulting parameters did not seem to follow any regular pattern.

5 Conclusions and future work

The study of staggered quantum walks in the ZX-calculus, as described in the previous sections, illustrates the ways in which a (diagrammatic) algebraic calculus can guide the optimization of quantum programs. The lesson is well-known in classical software engineering: building formal models of programs and reasoning about them in a calculational way is key to increase performance through correctness-preserving transformations. The same will be similarly true in the emerging design discipline for quantum algorithms.

The exercise showed that the original, 'intuitive' implementation of a staggered quantum walk can be heavily optimized with respect to both the total number of gates and the T-count value, therefore making the staggered model a suitable algorithmic tool in the NISQ era[Pre18]. The exercise also lead to the identification of an alternative formulation of the evolution operator with a significant reduction in the number of gates involved and thus suitable for running on more limited quantum processing units. As mentioned in the previous section, however, a number of issues, related to determining the suitable parametrization scheme and better understanding the structure of the initial and final stages in the resulting circuit, still require further investigation. Similarly, it is not completely clear how the choice of the initial state influences how well the operator approximates the model evolution.
